Directions in vehicle efficiency and emissions

This paper provides a general review of light-duty (LD) and heavy-duty (HD) regulations, engine technology, and key emission control strategies. The US is placing a stronger emphasis on laboratory emissions, and the LD regulations are about an order of magnitude tighter than Euro 6, but Europe is focusing on real-world reductions. The California HD low-NOx regulation is advancing and may be proposed in 2017/18 for implementation in 2023+. The second phase of US HD greenhouse gas regulations propose another 25-30% tightening beyond Phase 1, beginning in 2021. LD and HD engine technology continues showing marked improvements in engine efficiency. LD gasoline concepts are closing the gap with diesel. HD engines are demonstrating more than 50% BTE using methods that can reasonably be commercialized. LD and HD diesel NOx technology trends are also summarized. NOx storage catalysts and SCR combinations are the lead approach to meeting the LD regulations. Numerous advanced NOx technologies are being evaluated and some promise for meeting the California HD low NOx targets. Oxidation catalysts are improved for both diesel and methane oxidation applications. Gasoline particulate filters (GPF) are the lead approach to reducing particles from gasoline direct injection (GDI) engines. They reduce PAH emissions, and catalyzed versions can be designed for low back pressure. Regeneration largely occurs during hot decelerations.

Key words: greenhouse gases, vehicle emissions, regulations, engines, aftertreatment, NOx, diesel oxidation catalyst, selective catalytic reduction, diesel particulate filter, gasoline particulate filter

1. Introduction

The challenges are significant in reducing vehicular criteria pollutants and greenhouse gases to meet tightening regulations around the world. Multitudes of papers and presentations are given annually to advance the understanding and technologies.

This paper focuses on recent key developments related to emissions for both diesel and gasoline engines in the automotive and heavy-duty markets. It begins with an overview of the major regulatory developments covering criteria pollutants and CO2. Then, a high-level review is provided of engine technologies, starting with light-duty gasoline and diesel engines, and then heavy-duty diesel engines. In this section, only broad developments are covered with the intent of summarizing the directions and emissions challenges for exhaust technologies. Next, the paper covers lean NOx control, oxidation catalysts, diesel and gasoline PM filters, and closes with representative papers on gasoline emission control.

This review is not intended to be all-encompassing and comprehensive. Representative papers and presentations were chosen that provide examples of new, key developments and direction.

2. Regulations

Figure 1 shows the relative light-duty (LD) gasoline vehicle tailpipe non-methane hydrocarbon (NMHC) and NOx regulations for representative regions around the world. The emerging US Tier 3 regulations, which started phase-in in California (regulation LEV3) in 2015, are the tightest in the world, and are 85% to 90% (for diesel) tighter than the current Euro 6 regulations. The US also has much tighter durability requirements of 240,000 km versus 160,000 km for Europe. For the first time, China is proposing deviating from the European regulations with their China 6b regulations, which are 1/3 of the Euro 6 standards, proposed for 2023. Given the relative size and dominance of these two markets, it seems likely the rest of the world will eventually follow. Additionally, further tightening in the US is possible with California recently laying out a regulation roadmap for 2025+ suggesting converting the fleet average NMHC + NOx emissions of the 18 mg/km shown in the figure to a cap.

Europe also sees a need to reduce vehicular emissions, but is emphasizing tighter enforcement of current regulations by incorporating a real-driving emissions (RDE) regulation for NOx from light-duty diesel (LDD) and particles from gasoline direct injection (GDI) vehicles. Implementation is scheduled to begin in September 2017 with emissions being measured on roads using portable emissions monitoring systems (PEMS). By 2021, the RDE effective emissions are expected to be similar to the dynamometer certification limit values, versus values that averaged ~6x measured on 38 Euro 6 cars tested using the RDE protocol (1). For heavy-duty (HD) vehicles, the Euro VI regulations allow 10 mg/kWh PM (particle mass) and 460 mg/kWh NOx on the world-harmonized heavy-duty transient cycle. The US regulations are 30% looser on PM but about 40% tighter on NOx using the US transient cycle. Europe also added a particle number standard of 6 x 1011 particles/kWh on the transient cycle, essentially forcing the use of diesel particulate filters (DPF). Although not required to meet the PM regulation in the US, all heavy-duty trucks use DPFs to meet all aspects of the regulation. California is investigating further tightening the HD regulations by as much as an order of magnitude in the 2023-2027 timeframe, and the US EPA (Environmental Protection Agency) is considering following.

Shifting to greenhouse gases, Figure 2 shows a comparison of LD CO2 regulations around the world [2]. In this case...
Europe takes the lead, wherein the US generally harmonizes with a five-year delay. However, again in real-world driving the emissions improvements are different. European real-world CO\textsubscript{2} emissions as indicated using fuel consumption records on 600,000 vehicles were compared to certification values measured on the NEDC (New European Drive Cycle) [3]. The study found that model 2001 cars were emitting about 8% more CO\textsubscript{2} than indicated on the test cycle. But in 2014 this gap increased to 40%, with virtually no real-world CO\textsubscript{2} emissions improvements for models 2010 to 2014. The researchers attribute 75% of the 2014 gap to testing the vehicles on the dynamometer using the favorable end of allowable tolerances and procedures during certification testing. In the US, one estimate [4] is that automakers will need to triple their annual rate of improvement in vehicle efficiency (traction energy/fuel energy; ~22% in 2015) from 0.3% per year to 0.9% per year to meet the 2025 regulations.

On the HD side, the final stage of the US Phase 1 HD greenhouse regulation starts in 2017. The EPA (Environmental Protection Agency) finalized a Phase 2 rule that will build upon this and be phased in from 2021 through 2027 [5]. The main features of the rule are:

- Maintain separate engine and vehicle standards, but reweigh test cycles to better-reflect real-world operation. Engines should improve fuel consumption by ~4-6% from 2017 to 2027.
- Regulate trailers using a computer model of technology options such as aerodynamics, rolling resistance, and weight reduction.
- Include transmissions using modeling or integrated powertrain testing.
- Improved vehicle simulation model to regulate vehicle technologies.
- 18 vocational vehicle categories.
- Chassis dyno confirmation of reductions for some classifications.
- Regulate natural gas emissions from the crankcase and LNG (liquid natural gas) tanks.

Total CO\textsubscript{2} reductions from the large line-haul freight trucks and trailers is on the order of 25% from the 2017 Phase 1 baseline.

3. Engine developments

Figure 3 shows estimates of CO\textsubscript{2} reductions, emissions issues, and the status of representative LD engine technologies, relative to the basic turbo-charged direct-injection gasoline engine. Given the expense and market resistance to EV technologies (only < 5% hybrid market penetration 18 years after the first introduction), it seems reasonable that engine technology will be developed to the maximum practical potential and be combined with hybridization.

Figure 4 summarizes improvements and normalized cost of powertrain technologies to bring a Euro 5 platform to the EU and US CO\textsubscript{2} standards of 2020-22 [6]. Gasoline engines are closing the CO\textsubscript{2} gap with diesel. However, the incremental cost of the diesel improvements is considerably less than that of gasoline once a diesel powertrain investment is made. Also, hybridization is generally more expensive than engine improvements.

The impact of advanced engine concepts will affect exhaust gas temperatures, highlighting the challenge of increasing engine efficiency while reducing criteria pollutants. This can especially be problematic for diesel
engines. Pischinger [7] nicely summarizes the relationship between time, fuel consumption reductions and exhaust gas temperatures for the 2 liter class engines at a medium load point. Post-turbo temperatures dropped a remarkable 220°C (480°C to 260°C) from 2005 to 2015 while BSFC (brake specific fuel consumption) dropped 5%.

The most efficient engine to ever reach the development stage is the 2-stroke opposed piston diesel engine. Independent modeling work [8] shows a 13-15% incremental fuel consumption reduction relative to a state-of-the-art 2020 diesel 1.2 liter engine, confirming earlier reports from developers [9].

Moving to HD engines, the US EPA Phase 2 HD GHG proposal [5] lists some potential engine technologies and implementation timing needed to meet the regulation. Figure 5 shows the projected technologies and GHG reductions for the largest truck engines. Technologies that will be implemented at the highest rate by 2024 are reducing friction and other parasitic losses, improved aftertreatment, reduced pumping losses, and improved combustion. The incremental hardware cost relative to 2017 levels associated with these items is estimated by the EPA to be about $400-500 at maturity.

To help move these engine technologies forward, the US Department of Energy SuperTruck Program is now closing [10]. Common features independently developed by each of the four program participants to achieve 50% BTE engines (brake thermal efficiency = energy to crankshaft/energy in fuel) under road loads are:

- Engine efficiency: high efficiency turbochargers, friction reduction, reduced ancillary losses.
- Fuel Injection: high-pressure common rail.
- Combustion: higher compression ratio, optimized piston bowl redesign.
- Selective Catalytic Reduction (SCR) for NOx: higher efficiency deNOx, low ΔP.

Although Rankine cycle waste heat recovery gives the largest fuel savings, and it was used by all four participants to achieve 50% BTE, the other technologies are enough in combination to achieve the program goals.

4. NOx control

Light-duty diesel NOx control is being driven by the Euro 6 regulation (80 mg/km NOx on the World-Harmonize Light-Duty Test Cycle, WLTC), but the emerging RDE regulations are requiring even more NOx control, with conformity factors of 2.1x (multiple of the certification testing; 168 mg/km) in September 2017 and 1.5x (120 mg/km) in September 2020 for new engines. The current US regulations are about 50% tighter on a fleet average basis, but cars can certify higher as long as other cars (e.g., gasoline) certify lower than the average. The emerging US LD NOx regulations are about an order of magnitude lower than Euro 6.
The leading NOx architecture for both LD markets is the NOx storage catalyst (NSC) followed by an SCR catalyst either coated on a diesel particulate filter (DPF) or downstream from it, or both [11]. The NSC has good low-temperature performance, and generates NH3 during the rich desorption portion of the operating cycle, to replace or supplement urea injection to the SCR catalyst. Figure 6 shows some of the architectures [12]. Using only the NH3 coming from the NSC, a “passively” operated NSC+SCR system (no urea) reduces NOx nearly 80% on the WLTC, with all the cold start NOx reductions coming from the NSC, and only 7% of the total reductions coming from the SCR unit. Larger cars or higher-load operation may require urea as an addition NH3 source. With urea-based NSC+SCR systems, upwards of 90-95% cycle averaged deNOx efficiencies can be achieved. In city driving cycles the NSC removes about 2/3rd of the treated NOx, with the urea-SCR taking up the remaining third. Even on a highway cycle, the NOx burden is roughly evenly split between the NSC and SCR. For cold start applications, it is beneficial to locate the SCR catalyst as close to the engine as possible, so SCR catalyst coated onto the DPF is preferred.

Passive NOx adsorbers (PNA) release the NOx thermally (T > 180°C) rather than chemically (rich-lean cycling). In one study [13], about 10% of the engine NOx was removed on the NEDC, all of it in the cold start portion, by the passive NOx adsorber and converted in the SCR. NOx emissions are 25% lower than if a DOC (diesel oxidation catalyst) was used instead of the NOx adsorber. Improvements are coming. When palladium is added to a ZSM-5 zeolite, NOx can be stored at 50°C and released at 250-400°C [14]. The zeolite also adsorbs hydrocarbons, and it is thought the released HCs help in NOx reduction.

In the heavy-duty sector, the aftertreatment architecture has been essentially unchanged since about 2010: DOC + DPF + SCR + ASC (ammonia slip catalyst). These systems are now achieving > 96% cycle-averaged deNOx efficiencies on the cold and hot start composite transient cycles. However, to meet the future California HD low-NOx regulations that are being discussed with minimized GHG impacts, > 99% deNOx efficiency will be needed. In an interim report of a technical feasibility study, 20 mg/bhp-hr NOx was achieved in composite (cold plus hot start) US HD transient testing using a burner rig simulator of engine exhaust conditions [15]. Technologies employed included improved engine calibration, auxiliary heating during the cold start and low-load periods, PNA, SCR+DPF, heated
urea or gaseous NH₃ injection, more SCR volume, and/or a light-off SCR catalyst. Figure 7 shows some results and the two lowest-configurations with the lowest NOₓ.

5. Oxidation catalysts

Diesel oxidation catalysts (DOCs) play the role of pre-conditioning the exhaust for the complex downstream components. As such, DOCs are being designed for specific applications. Fundamentals are still being developed.

DOC formulations balance the palladium and platinum levels for optimum performance. The precious metal ratio, hydrocarbon and CO oxidation characteristics, and NOₓ formation were simultaneously simulated and tested in a light-duty DOC [16]. They looked at the LD application with a constant PGM (platinum group metals) loading of 4.2 g/liter (120 g/ft³). Increased platinum content improves n-C₃H₇, lean C₇H₈, and CO oxidation (except 100% Pt); but no NO oxidation, and the reduction back to NO by C₃H₈ and CO. Conversely, reactions promoted by increasing or pure palladium are CO and methane oxidation, C₄H₁₀ steam reforming, and rich C₃H₆ oxidation. A similar study [17] looked at HD applications. The results show a strong dependence of the NO oxidation on the catalyst oxidation state for different Pt-Pd DOCs. A model was developed and a case study demonstrated the capabilities of the model in designing an appropriate DOC for a given application.

Methane oxidation is important for natural gas engines, and can limit the application of these engines in Europe due to regulatory limits of 160 mg/kWh total HC on the transient cycle for compression ignition, and 500 mg/kWh methane for spark ignition engines. Methane is difficult to oxidize and the best commercial catalysts need T > 350°C to convert 50% of the methane. However, it was recently reported [18] that a platinum-palladium catalyst on a titania and ZSM-5 zeolite support that dropped this temperature to < 250°C.

6. Gasoline particulate filters

Converse to the US, the European Union has implemented a particle number (PN) standard for gasoline direct injection engines, 6E12 particles/km, tightening to 6E11 particles/km in 2017. In addition, the European Commission is likely to recommend maintaining these values in RDE testing, after taking into account measurement error. Improved fuel injection and other engine methods can be used to help meet these standards [19], but these methods can fail to meet the regulations as the engine ages, if engine deposits form [20], or if the car is driven in somewhat more aggressive drive cycles or is not warm [11]. Alternatively, gasoline particulate filters (GPFs) provide a robust solution. Further, poly-aromatic hydrocarbons may be strongly associated with the particles, and GPFs greatly reduce these [11]. Hence, GPFs are a leading technology being evaluated to meet the European and proposed Chinese PN regulations.

Earlier GPF work focused on bare filters, but high porosity filter substrates can make adding a three-way catalyst to the filter attractive [21]. Back pressure with a “four-way catalyst” is only 10% more than that of the base TWC system [22]. Engine performance impacts after 160,000 km is minimally affected [21], with only 2.5% loss of peak power and < 1% loss of peak torque, with no deterioration in fuel consumption.

Regarding filter regeneration, a GPF was preloaded with a representative soot surrogate and installed in the under-floor (UF) position on a car [23]. Figure 8 shows actual and simulated results. The soot is mainly burned during the lean deaccelerations. At 30 km/h there was no soot burn, but nor was there soot accumulation. Also shown in the figure is a simulated case when the filter is in the close-coupled (CC) position. Soot burn is rapid due to the higher temperatures.

Fig. 8. Measured and simulated burning of soot in under-floor GPFs for three different average speed regimes [23]

7. Conclusions

The LD regulations in representative markets are compared. The emerging US Tier 3 regulations (starting in 2017) are about an order of magnitude tighter than the current Euro 6 regulations. Europe is shifting focus to real-world driving emissions (RDE) for LD diesel NOₓ and GDI (gasoline direct injection) PN (particle number) in 2017. China has been following the EU, but it is proposing standards for 2023 that are 1/3 of Euro 6. LD GHG (greenhouse gas) regulations are also compared, with Europe implementing the tightest regulations. However, real-world reductions in the EU are significantly less than indicated by the regulation.

Europe and US currently have similar HD regulations, but California will be tightening down on NOₓ beginning in about 2023-27. The US EPA Phase 2 HD greenhouse gas standards for 2021-27, calling for a nominal 4-6% tightening on engine CO₂ and 15-25% for the whole truck, depending on class.

Gasoline engines are developing rapidly, slowly closing the gap with diesel, but LDDs are making incremental gains that are very cost effective versus other options automakers have. Exhaust temperatures are decreasing as engine efficiency improves. There are numerous incremental strategies being used on HD engines to approach or attain 50% BTE.

Leading lean NOₓ reductions for heavy- and light-duty diesel engines is generally reviewed. SCR filters are central to the LD for meeting the EU RDE and US Tier 3 regulations. LD systems are using NOₓ storage catalysts (NSCs).
for cold start and downstream SCR systems on filters and/or in traditional flow-through designs. Advanced prototype HD systems are being evaluated for meeting the California HD low-NO\textsubscript{x} objectives. Some achieve < 20 mg/bhp-hr NO\textsubscript{x} on a simulated HD FTP transient cycle.

Understanding on diesel oxidation catalysts continues to evolve. LD and HD simulations enable proper design to meet a variety of needs. An experimental catalyst was reported that oxidizes methane at ~250°C, about 100°C lower than the best commercial catalysts.

Gasoline particulate filters (GPFs) are essentially needed to meet the Euro 6c and RDE regulations coming in 2017. Toxic PAH (polycyclic aromatic hydrocarbon) emissions are reported from GDI vehicles and reduced using GPFs. GPF regeneration is characterized. Almost all the required burning of soot occurs during lean decelerations. Soot levels on GPFs reach an equilibrium loading in urban driving.
